ABSTRACT

cleidocranial dysplasia (CCD) is an autosomal dominant skeletal dysplasia characterised by abnormal clavicles, patent sutures and fontanelles, supernumerary teeth, short stature, and a variety of other skeletal change. Cleidocranial dysplasia is caused by mutation in the gene on 6p21 encoding transcription factor CBFA1, i.e. runt-related transcription factor 2 (RUNX2). Individuals with CCD should be followed by either a team of specialist or by individual specialist familiar with the problems that can be associated with this condition. J Clin Exp Invest 2012; 3(1): 133-136

Key words: Cleidio-cranial dysplasia, supernumerary teeth, diagnosis

INTRODUCTION

Cleidocranial Dysplasia (CCD) is a rare congenital disorder of bone with an autosomal dominant hereditary mode of inheritance with complete penetrance, but variable expressivity. This condition is characterized by clavicular aplasia or deficient formation of the clavicles, delayed and imperfect ossification of the cranium, moderately short stature, and a variety of other skeletal abnormalities. The principal oral manifestations are a delayed exfoliation of primary teeth, delayed or multiple impactions of the permanent dentition, and multiple impacted supernumerary teeth.¹

Cleidocranial dysplasia was first described in a patient with congenital absence of clavicle in 1765 by Martin.² Marie and Sainton coined the term cleidocranial dysostosis in 1898, although descriptions of the disorder can be traced back to the 1760s.³ The term dysostosis means defective ossification or defect in the normal ossification of fetal cartilages (Gr. osteon - bone). In dysostoses the distribution follows a defect in ectodermal or mesenchymal tissues. Rarely are all bones involved. As derived from the Greek, dysplasia refers to abnormality of development or "ill formed" (Gr. plassein - to form); in pathology it means alteration in size, shape, and organization of adult cells.

The prevalence of cleidocranial dysplasia is one per million with complete penetrance and variable expressivity, but it is most likely under diagnosed because of the relative lack of medical complications in comparison with other skeletal dysplasia's. It may be discovered at any age, but the cranial deficiencies may be noticed at birth. Both sexes are affected to an approximately equal extent. The defect often appears in several successive generations.⁴

Etiology

The etiology though not completely known is thought to be due to a CBFA1 (core binding factor activity 1) gene defect on the short arm of chromosome 6p21 (5,8). CBFA1 is essential for differentiation of stem cells into osteoblasts, so any defect in this gene will cause defects in the membraneous and endochon-
It affects bones of intramembranous origin and endochondral bone formation of long bones, there is also failure of midline ossification. Involvement of non-membranous bones is also well recognized. Keats in 1967 reported the involvement of long bones, the spine and the base of the skull. Subsequently Jarvis and Keats extensively reviewed the skeletal anomalies in CCD.

According to Yoshida et al. Cleidocranial dysplasia could result from a much smaller loss in the RUNX2 function. They also implied that an inherent mechanistic commonality exists between the skeletal growth and the dental development in their dependencies on the RUNX2 activity, despite the tremendous apparent dissimilarities of these two organogenesis processes. If the type of mutation in RUNX2 is known in advance, we could predict the supernumerary teeth for an individual to allow the early initiation of the necessary treatment.

Clinical features
People with CCD have a characteristic facial appearance. They tend to have a short head from front to back (brachcephaly) and a prominent forehead (frontal bossing). There is typically delayed closure of fontanelles, and some adults with CCD have open fontanelles. The eyes are widely spaced, and the nasal bridge is often flat. The neck appears long, and the shoulders are narrow and down-sloping.

Characteristically, patients with cleidocranial dysplasia, show prolonged retention of deciduous dentition and delayed eruption of permanent teeth. Adults with cleidocranial dysplasia have mixed dentition in their oral cavities. In addition, patients with this condition, frequently show a large number of unerupted supernumerary teeth, often mimicking a premolar. As many as 63 unerupted supernumerary teeth have been documented in one patient.

Reason for the formation of multiple supernumerary teeth is still unknown. Maxilla is also underdeveloped along with ill-formed paranasal sinuses. Skeletal Class III tendency / mandibular prognathism in CCD can be attributed to its uninterfered growth due to hypoplastic maxilla and upward and forward mandibular rotation. This condition is of clinical significance to every dentist due to the involvement of the facial bones, altered eruption patterns and multiple supernumerary teeth.

The most characteristic and pathognomic skeletal feature is that one or both clavicles are frequently partially or in 10% cases completely absent. Usually rudimentary sternal and acromial stubs are present and the mid-clavicular position is absent. Clavicular deformity along with the dysplastic muscle attachments give rise to elongated neck, narrow drooping and hypermobility of shoulders with tendency to approximate shoulders anteriorly.

Clavicle is the first bone to be ossified in the 6th week of fetal life and is thus the most often affected bone.

Incomplete ossification of contours of embryonic vertebral arches account for various vertebral deformities like spina bifida, kyphosis, scoliosis, hemivertebra and cervical ribs. Patients with cleidocranial dysostosis and progressive scoliosis should have CT scan and MRI scan to rule out the presence of syringomyelia.

Radiological findings
The radiological appearance of CCD is almost sufficient for diagnosis. Various features that are evident on panoramic radiographs are multiple unerupted abnormal teeth, a narrow ascending ramus, a slender and pointed coronoid process, a thin zygomatic arch with a severe downward tilt, small or absent maxillary sinuses, coarse trabeculation of the mandible, cyst formation with supernumerary teeth mainly in the premolar region, and increases density of the alveolar crestal bone over unerupted teeth.

Skull radiographs show brachycephaly, a persistently open anterior fontanelle, multiple wormian bones, open skull sutures, small sphenoid bones, and calvarial thickening especially over the occiput and wormian bones. This radiography shows a narrow thorax, oblique ribs and absence of clavicle.

Differential Diagnosis
The differential diagnosis of CCD includes crane-Heise syndrome, mandibulaacral dysplaxiz, pycnodysostosis, yunis varon syndrome, CDAGS syndrome and hypophosphatasia etc. These conditions may share some characteristics with CCD, however all these are autosomal recessive disorders and have other specific features. Some of these conditions may result from mutation in genes that affect the action of RUNX2 on its downstream targets.

Management
In terms of dental management of CCD, several approaches have been reported over the years. The option of no treatment was common in the past. Eventuation followed by provision of dentures has also been suggested. Some regard this approach as too invasive, especially considering the extensive bone loss experienced after removal of teeth in a patient already deficient in alveolar bone. Pusey and Durie suggested removal of only the erupted
teeth and use of a removable prosthesis to minimize alveolar bone loss. However, subsequent eruption of retained teeth can require further surgery and modification of the prosthesis.22

Early identification of the syndrome permits the planning of dental treatment by selecting the teeth that should be removed. Sato23 suggests the use of a three-dimensional method of locating the position of impacted supernumerary teeth, insisting upon the importance of the removal of the supernumerary teeth and the planning of an orthodontic treatment that will allow for occlusion of the retained teeth. Davies26 recommends a method where orthodontic forces may be applied to un-erupted permanent teeth moving them into a satisfactory, functional and aesthetic position. Occasionally, when the teeth fail to erupt after the removal of supernumerary teeth and orthodontic traction, a combination of orthodontic-prosthodontic treatments is necessary.27

If bone density is below normal, treatment with calcium and vitamin D supplementation should be considered. Preventive treatment for osteoporosis should be initiated at a young age since peak bone mineral density is achieved in the second and third decade. So, early diagnosis of CCD is beneficial for prompt intervention which will greatly influence the better restoration of craniofacial aesthetics and function.30

Individuals with CCD should be followed by either a team of specialist or by individual specialist familiar with the problems that can be associated with this condition.3 In young children with CCD, the fontanels may be so large as to warrant the wearing of a helmet to protect the brain. Hearing tests should be performed at birth and regularly (at least yearly) thereafter.27 Affected infants should receive their first dental evaluation by one year of age, preferably by a dentist who treats children with complex problems. Of note, it has been shown that extraction of primary teeth does not hasten the eruption of permanent teeth in this condition. Children with CCD may have recurrent otitis media (middle ear infection) related to abnormal formation of palate and/or Eustachian tube dysfunction; this may necessitate the placement of tympanostomy tubes.14,15 Individuals with CCD are more likely to have upper airway obstruction, and sleep habits must be carefully monitored. Regular snoring and (or) restless sleep may warrant a sleep study. Occasionally, an affected individual may have a narrow crest that causes respiratory disease.25 Finally, it is important to note that people with CCD are expected to be shorter than their typical peers and family members. With proper anticipatory guidance, people with CCD usually lead healthy and productive lives.
